Quality, variable markups, and welfare: A quantitative general equilibrium analysis of export prices

Haichao Fan, Yao Amber Li, Sichuang Xu, Stephen R. Yeaple

Abstract

Modern trade models attribute the dispersion of international prices to physical and man-made barriers to trade, to the pricing-to-market by heterogeneous producers and to differences in the quality of output offered by firms. This paper presents a tractable general equilibrium model that incorporates all three of these mechanisms. Our model allows us to confront Chinese firm-level data on the prices charged and revenues earned within and across markets. We show that all three mechanisms are necessary to fit the distribution of prices and revenues across firms and markets. Accounting for endogenous quality heterogeneity across firms and markets is shown to be critical for the response of prices to trade and tariff shocks.

1. Introduction

The literature on quantitative general equilibrium models has blossomed in recent years. The popularity of these models is driven by their simplicity, by their ease of calibration, and by their flexibility to be adapted for the analysis of the impact of a wide variety of policies. Further, as shown by Eaton et al. (2011) these models can successfully confront firm-level microdata on the distribution of sales within and across countries. One feature of the microdata that has received less attention in the development of quantitative general equilibrium models is the joint distribution of firm-level prices and sales within and across countries. As has been shown in existing descriptive work (e.g. Manova and Zhang, 2012), firms from a given source country charge very different prices across countries.

In this paper we develop a simple quantitative general equilibrium model with heterogeneous firms that has been designed to confront the joint distribution of firm-level prices and sales. Variations in prices within-firm, across-country stem from the interaction between trade costs that vary between countries, firms’ decisions to price-to-market, and firms’ endogenous provision of goods of different quality to different countries. Our model includes all three of these features. With respect to trade cost, we explicitly allow for both standard iceberg (ad-valorem) trade costs and specific (fixed per unit) trade costs. This is natural because both types of trade costs are likely to be a feature of the constraints facing exporters in the real world and because the
interaction between the two types of trade costs has been shown to affect the quality decision of firms (Hummels and Skiba, 2004).

We also allow firms to choose the quality of goods that they provide to each market that they serve. We assume that the marginal cost of production is increasing in output quality and decreasing in firm productivity. Because specific trade costs are not increasing in the quality of goods sold, firms can lower their cost of serving markets with high specific trade costs by upgrading quality, and the incentive to do this is rising in a firm's productivity because these firms sell the largest number of units. Hence, our specification delivers a "Washington-Apples" effect that varies in strength across both countries and firms and so provides a mechanism to fit the joint distribution of prices and revenues.\(^1\)

With respect to pricing-to-market, we follow Jung et al. (2019) by assuming CES-like preferences that have been generalized to allow for an endogenous "choke price". Firms in our model first minimize quality-adjusted marginal costs and then set quality-adjusted prices to maximize profits in each market that they serve. While the correlation between quality-adjusted prices and quality-adjusted revenue will be negative due to the optimal markup choices of the firm, the correlation between observed (unadjusted) prices and (unadjusted) revenues will be positive as in the data.

Combining firm heterogeneity, endogenous quality, and pricing-to-market all together, our simple model generates rich predictions regarding across-firm and across-country price variations. Qualitatively, our model is consistent with a well documented range of facts regarding the joint distribution of prices across firms and across countries. Further, the model can capture the positive relationship in the data between a firm's price and the its revenue. More importantly, the key contribution of our model is the parsimonious and highly tractable framework which allows us to conduct a quantitative general equilibrium analysis.

Our paper also has novel implications for the estimation of gravity equations. A large class of models generates gravity equations in which the elasticity of trade flows with respect to trade costs reveals key structural parameters (Arkolakis et al., 2012; Arkolakis et al., 2019). Our model also generates a gravity equation in which the appropriate measure of trade costs is the geometric average of specific and iceberg trade costs where the weights reflect the elasticity of marginal cost with respect to quality. In standard models a common way to estimate the trade elasticity using tariffs, which are generally ad-valorem, as a measure of trade costs (e.g. Head and Mayer, 2014). In our framework with specific trade costs, this calibration strategy necessarily leads to an underestimate of the key macro elasticity. We calibrate our model to aggregate trade flows (gravity) and to the joint distribution of firm-country level price and sales from Chinese customs data.

Our model also contributes to our understanding of the response of prices to trade cost shocks. Much recent work analyzes the markup responses of firms to changes in trade policy (e.g. De Loecker et al., 2016; Jung et al., 2019). In our setting, shocks to trade costs affect firm-level prices through multiple mechanisms. On the one hand, firms respond to any shock to quality-adjusted marginal costs by changing their markups. On the other hand, firms also adjust the quality of their output and this induces a price response as quality-adjusted marginal costs change. To illustrate the potential for quality adjustment to be confused for adjustment in markups, we consider a comparative static exercise in which we alternatively shock specific and iceberg trade costs to each Chinese trading partner by enough to lower trade by 5% These shocks have equivalent welfare effects but generate very different price responses. Because increases in specific trade costs induce firms to raise their quality, they lead to exaggerated price increases, whereas shocks to ad valorem trade costs induce firms to lower the quality of the goods they provide and so lead to small changes in prices. Hence, the model demonstrates the need to know the nature of trade shocks before making predictions over the associated price changes.\(^2\) This is important as it shows how micro-econometric models that neglect specific trade costs may be misspecified.

Our paper contributes to two strands of the literature that seek to understand the causes and implications of international prices. First, our focus on endogenous quality puts our paper into a literature that includes the recent paper by Feenstra and Romalis (2014) who provide a monopolistic competition model that has been designed to estimate the quality of goods traded and sold domestically with the intention of purging price indices of quality variation across countries. As the authors are working with country-level data, they do not develop their model to confront the joint distribution of firm-level prices and sales, which is the focus of our paper.\(^3\)

Our paper also contributes to the literature featuring variable markups. These papers include Jung et al. (2019) and Atkeson and Burstein (2008). As in Jung et al. (2019), we consider non-homothetic preferences and a market structure that gives rise to variable markups across firms. Relative to their paper, we also consider vertically differentiated products, quality upgrading opportunities, and specific trade costs that give rise to the "Washington Apples" effect. Our framework, therefore, allows for much of the variation across countries and firms to be attributed not to variation in market power but to variation in quality of output. Allowing for quality upgrading helps to make the model with variable markups more consistent with the well-known pattern in the data that the most successful exporters tend to charge the highest prices (e.g. Manova and Zhang, 2012; Harrigan et al., 2015). Moreover, our framework highlights the differential effect of specific and ad valorem trade costs on the international distribution of prices.

In the literature, models that feature firm heterogeneity, endogenous quality, and variable markups are rare. An important exception is Antoniades (2015) who embeds endogenous quality into the model of Melitz-Ottaviano (Melitz and Ottaviano, 2008). The focus of the Antoniades’s model is on the role of market size and scale economies in driving endogenous quality and so it lacks the “Washington Apples” mechanism that is our focus. Nevertheless, the model presented in Antoniades (2015) generates a rich set of predictions that can be qualitatively consistent with many of the facts presented in our paper. The Antoniades paper does not confront its model with the data, however, and doing so would be difficult given the complex interaction in the model of its parameters and endogenous variables.

Finally, our paper is also related to the recent work by Hottman et al. (2016) who allow for both market power and quality heterogeneity to drive price dispersion across local prices in the United States. They find that a very substantial portion of heterogeneity in market shares can be attributed to quality heterogeneity but with firms’ strategic pricing decisions also playing a non-trivial role. By considering a more parsimonious setting, we can conduct an analysis of the role of markup and quality dispersions to an international setting. In addition, we follow Arkolakis et al. (2019) and derive a sufficient-statistic-type welfare formula for the gains from trade with the presence of both endogenous quality and variable markups.

The remainder of this paper is organized into six sections. In Section 2, we develop a series of stylized facts concerning the international pricing behavior of Chinese firms that we will use to calibrate our model. In Section 3, we present a simple, quantitative general equilibrium model that is able to rationalize these stylized facts and that can be quantified with features of our data. In Section 4, we describe how

\(^1\) Our formulation adapts Feenstra and Romalis (2014) to be more in line with the initial formulation in Hummels and Skiba (2004). Feenstra and Romalis (2014) do not adapt their mechanism to confront firm-level data.

\(^2\) On a related note, variations in prices across countries are occasionally used to measure trade costs. If bilateral trade costs vary in their mixture of specific and ad valorem costs, much of the observed differences in prices would be due to quality upgrading rather than absolute levels of trade costs.

we solve, calibrate and simulate our benchmark model. In Section 5, we assess the model’s fit to the data, and derive an expression for the welfare gains from trade shocks to show the model’s quantitative implications for the gains from trade. In Section 6, we illustrate how specific and ad valorem trade shocks that have identical effects on welfare and on trade volumes have very different effects on prices. Finally, in Section 7, we provide concluding comments.

2. Stylized facts

In this section, we present a series of facts that suggest the need for a model that incorporates firm heterogeneity, variable markups, and endogenous quality in order to understand the distribution of prices across firms and markets.

2.1. Data

To document the stylized facts regarding export prices across destinations and across firms within the same destination, we use two micro-level databases and one aggregate-level cross-country database. Specifically, these are (1) the transaction-level export data from China’s General Administration of Customs; (2) the annual survey of industrial firms from the National Bureau of Statistics of China (NBSC); (3) the CEPII Gravity database that provides destination countries’ characteristics such as population, GDP per capita, and distance to China. We use data for the year 2004 to be consistent with the calibration exercise later.

The China’s Customs database records each export and import transaction for the universe of Chinese firms at the HS8 product level, including values, quantities, products, source and destination countries, firm contacts (e.g., company name, telephone, zip code, and contact person), enterprise types (e.g., state owned, domestic private, foreign invested, or joint venture), and customs regimes (e.g., ordinary trade, or processing trade). We aggregate each transaction-level data to various levels, including firm-HS6–destination country, firm-HS6, or HS6-country for further analysis. We compute unit values (i.e., export values divided by export quantities) as a proxy for export prices and focus on ordinary exporters.

To characterize firms’ attributes such as TFP, employment, capital intensity, and wage, we use the NBSC firm-level data from the annual surveys of Chinese industrial firms. This database contains detailed firm-level production, accounting and firm identification information for all state-owned enterprises (SOEs) and non-state-owned enterprises with annual sales of at least 5 million Renminbi (RMB, Chinese currency). We use merged data of both the Customs data and the NBSC firm survey data when firms’ characteristics are needed.

2.2. Empirical regularities

In this subsection, we report several stylized facts concerning export prices across destinations and across firms within the same destination as well as the number of firms that export to each destination. As we argue below, to be consistent with all of these facts requires a model that incorporates both variable markups and quality heterogeneity to understand the distribution of prices across firms.

To calibrate our model, we construct bilateral trade shares following the method described in Osca (2014) based on CANTAP 9 Data Base for the year 2004 (see Section 4 for more details). Processing traders have very little control over the prices that they receive for their goods and are often the affiliates of foreign firms who directly control the prices in transactions. This is the key reason that processing traders are excluded from this analysis.

Due to some mis-reporting, we follow Cai and Liu (2009) and use General Accepted Accounting Principles to delete the unsatisfactory observations in the NBSC database. See Fan et al. (2015) for more detailed description of data and the merging process.

The existing literature has documented many of these facts separately. We present them here to show that they also hold in the Chinese data and to refresh readers’ memories as to the features of the distribution of prices across markets and firms.

2.2.1. Fact 1: Export prices are higher in developed countries

Based on the whole customs data in 2004, Table 1 reports the regression results using (log) export prices as the dependent variable and destination country’s GDP per capita, its population, and its distance to China. Columns 1–2 and 3–4 use the prices at the firm-HS6-country level and the HS6-country level, respectively. The coefficients on GDP per capita in all specifications are positive and statistically significant, indicating that export prices increase in destination’s income (e.g., Manova and Zhang, 2012). To better control for country-level characteristics, we include the destination country’s GDP per capita in columns 1 and 3, while in columns 2 and 4, we further control for population and distance. Comparing odd columns with even columns, we find that adding population and distance would not affect our results qualitatively.

In Fig. 1, we plot the mean residuals of each destination from regressing log export prices on product fixed effects and log destination GDP per capita as well as destination’s population and distance. The data reveal a positive relationship between export prices and destination income.

2.2.2. Fact 2: A larger number of firms export to developed countries

We now turn to the number of exporting firms in different destinations. Table 2 reports the results of regressing the logarithm of the number of firms that export to each HS6-country (in columns 1–2) and each country (in columns 3–4) on destination country’s GDP per capita, including product fixed effects in columns 1–2 and further controlling for destination’s population and distance to China in columns 2 and 4. The significantly positive coefficients on the log of GDP per capita suggest that more firms export to richer destinations. Fig. 2 further supports the following finding by plotting (log) firm number at each destination against destination’s income.

The dependent variable in specifications (1)–(2) is the (log) price at the firm-HS6-country level, and in specifications (3)–(4) is the (log) price at the HS6-country level. All regressions include a constant term.

We begin with two sets of facts that suggest that competition is lower in developed countries and that lower competition induces firms to charge high markups and to allow relatively less competitive firms to enter the market.

8 The coefficient on distance is significantly positive. This result is consistent with the “Washington Apple” effect of Hummels and Stibis (2004). As for population, the regression based on the data presents a significantly positive coefficient on population. A reasonable interpretation of this result is that large populations are associated with greater competition and that this induces firms to upgrade the quality of goods sold in those markets (Antoniades, 2015).

2.2.3. Fact 3: More productive firms charge higher export prices

To present export prices across firms, we use the merged data of the Customs and the NBSC in 2004 in Table 3 and report the results obtained by regressing export prices on firm productivity, and other firm-level controls, such as employment, capital intensity, and the wage it pays. The measure of firm productivity is revenue based TFP, estimated by the augmented Olley–Pakes’ (Olley and Pakes, 1996) approach by allowing a firm’s trade status and the WTO shock in the TFP realization, as in Amiti and Konings (2007). In columns 1–2, we use firm–HS6-country level price and include product–country fixed effect; in columns 3–4, we use firm–HS6 price and include HS6 product fixed effect. We do not control for employment, capital intensity and wage in columns 1 and 3, while in columns 2 and 4 we add those firm-level controls to show the robustness of our regression results. The coefficient on firm’s TFP are all significantly positive, which is consistent with the quality-and-trade literature that high-productivity firms charge higher prices (e.g., Fan et al., 2015). Fig. 3 also plots export prices against firm’s TFP by regressing firm–HS6 level export prices on HS6 product fixed effects and then plotting the mean residuals for each firm.

Table 3 and Fig. 3 show that more productive firms charge higher prices. It is also true that they earn higher revenues in each market as well so that the correlation between firms’ export revenues and their export prices is positive (See Table 7 and Fig. 6 later in the text).

2.3. Discussion

The facts presented in this section suggest several mechanisms are necessary to understand the distribution of prices. Facts 1 and 2 suggest that developed countries are systematically less competitive than less developed countries. Prices are higher there within firm-product, and this suggests that markups are higher there. Second, the number of firms that can survive in richer markets suggests a lower level of competition. In models with variable markups, this would be due to a higher choke price. Fact 3, however, suggests a need for quality heterogeneity as well. Larger, more productive firms charge higher prices and this is consistent with quality upgrading on their part. Further, some of the gradient in prices charged in richer markets may be due to higher quality goods being sold there. Finally, the results of Hummels and Skiba (2004) strongly argue for the need to incorporate quality variation in order to understand the “Washington Apples” effect. We now layout a simple model that can capture these facts.

3. Model

In this section, we introduce and solve our model. We first introduce the demand side of the model and solve for the optimal markup as a function of a firm’s quality of output and marginal cost of production. We then endogenize quality choice and characterize a firm’s decision to enter into a given market as a function of its heterogeneous cost draws. Third, we solve for the implied aggregate variables and close the model with labor market clearing/trade balance.
the perception of quality. We denote the source country by $\Omega_j$. Formulatively, we extend the preference system considered by Jung et al. (2019) augmented such that varieties vary in their perceived quality. We denote the source country by $i$ and the destination country by $j$. Consumers in country $i$ have access to a set of goods $\Omega_i$, which is potentially different across countries. Specifically, the representative consumer has preferences of:

$$U_i = \left[ \sum_l \int_{\omega \in \Omega_i} \left( q_{ij}(\omega) x_{ij}(\omega) + X \right)^{\alpha - 1} - X^{\alpha - 2} \right] \; d\omega$$

where $\alpha > 1$ is the elasticity of substitution, $x_{ij}(\omega)$ is the quantity of variety $\omega$ from country $i$ consumed by the representative consumer in country $j$, $q_{ij}(\omega)$ is its quality, and $X=0$ is a constant.

Utility maximization implies that the demand curve for variety $\omega$ is given by:

$$x_i(\omega) = x_i^{\omega}(\omega) L_j = \frac{L_j}{q_{ij}(\omega)} \left[ y_j + \frac{P_j}{p_{ij}(\omega)} \right]^{-\frac{1}{\alpha}}$$

where $p_{ij}(\omega)$ is the price of output from country $i$ to country $j$, $P_j = \sum_{k \in \Omega_j} \sum_{\omega \in \Omega_i} p_{ij}(\omega)/q_{ij}(\omega) d\omega$ and $P_j = \left( \sum_{k \in \Omega_j} p_{ij}(\omega)/q_{ij}(\omega) \right)^{-\frac{1}{\alpha}}$ denote aggregate price statistics, $y_j$ is the representative consumer’s income, reflecting GDP per capita in the destination country (see Appendix A for detailed derivation).

To simplify our discussion and to keep our notation compact, we define the quality-adjusted price charged by firm $\omega$ from country $i$ selling in market $j$ to be $\tilde{p}_{ij}(\omega) = p_{ij}(\omega)/q_{ij}(\omega)$, and we define the country $j$ “choke” price level to be $\tilde{p}_j = \left( y_j + \frac{P_j}{x_p^{\omega - 0}} \right)^{\frac{1}{\alpha}}$. Everything else equal, high nominal per-capita incomes and higher prices imply higher choke prices facing individual firms.

We thus can write quantity, sales, and profit for a given variety exported from $i$ to $j$ as follows,

$$x_{ij}(\omega) = \frac{q_{ij}(\omega)}{p_{ij}(\omega)} \left[ \left( \frac{\tilde{p}_{ij}(\omega)}{P_j} \right)^{-\alpha} - 1 \right]$$ (3)

$$r_{ij}(\omega) = \frac{q_{ij}(\omega)}{p_{ij}(\omega)} \left[ \frac{\tilde{p}_{ij}(\omega)}{P_j} \right]^{-\alpha} \left( \frac{\tilde{p}_{ij}(\omega)}{P_j} \right) - 1$$ (4)

$$\pi_{ij}(\omega) = \frac{q_{ij}(\omega)}{p_{ij}(\omega)} \left[ \frac{\tilde{p}_{ij}(\omega)}{P_j} - c_{ij}(\omega) \right] \left[ \left( \frac{\tilde{p}_{ij}(\omega)}{P_j} \right)^{-\alpha} - 1 \right]$$ (5)

where $c_{ij}(\omega) = c_{ij}(\omega)/q_{ij}(\omega)$ is the quality-adjusted marginal cost and $c_{ij}(\omega)$ is the marginal cost of production. Given the quality-adjusted marginal cost, firms maximize their profits.

Taking as given the pricing behavior of all other firms, the monopolistically competitive producer of variety $\omega$ chooses its quality-adjusted

![Fig. 2. Firm Mass increases with destination income. Notes: Destination-level firm number (in logarithm) are drawn against destination’s (log) GDP per capita by controlling for destinations’ population and distance.](image-url)
price of the good. The first-order condition for profit maximization implicitly yields the optimal price $p_{ij}(a)$ which satisfies:

$$\alpha (1) = \frac{\partial \ln p_{ij}(a)}{\partial a}$$

Note that the optimal prices and optimal profits depend only on the quality-adjusted marginal cost of production. In the next subsection, we endogenize a firm’s choice of its quality-adjusted marginal cost of production.

3.2. Quality and production

Firms are heterogeneous in productivity $\varphi$. Following Feenstra and Romalis (2014), for a firm from country $i$ with productivity $\varphi$ requires $l$ of labor produce one unit of output with quality $q$ according to the production function:

$$l = q_{ij}$$

where $\eta > 1$ is a measure of the scope for quality differentiation. In addition, a firm from country $i$ that wishes to sell its product in country $j$ must incur two types of variable shipping costs. The first, $\tau_{ij} \geq 1$, is the standard iceberg-type shipping cost which requires $T_{ij}$ units to be shipped for one unit to arrive. The second, $T_{ij}$, is a per-unit shipping cost (a specific trade cost). For simplicity, we assume that specific trade costs are in terms of country $i$ labor.

For a firm from country $i$ of productivity $\varphi$ that has received country $j$’s idiosyncratic cost shock $\varepsilon$, the marginal cost of supply one unit of quality $q_{ij}$ to country $j$ is

$$c_{ij}(\varphi, \varepsilon) = \left( \hat{T}_{ij}w_{i} + w_{i}T_{ij}q_{ij}^{\eta} \right) \varepsilon$$

where $\tau_{ij}$ is ad valorem trade cost and $T_{ij}$ is a specific transportation cost from country $i$ to country $j$.

Hence, the quality adjusted marginal cost of production is given by

$$c_{ij}(\varphi, \varepsilon) / q_{ij} = \left( \hat{T}_{ij}w_{i} + w_{i}T_{ij}q_{ij}^{\eta} \right) \varepsilon / q_{ij}$$

(7)

As will be obvious in a moment when solving for optimal quality choice by firm this formulation has several desirable features. First, it will exhibit the “Washington Apples” effect: higher specific trade costs will induce firms to upgrade their quality. Second, it will be consistent with the well documented fact that more productive firms charge higher prices (e.g. Kugler and Verhoogen (2009), Manova and Zhang (2012)). Third, it will prove to be highly tractable, allowing us to avoid the tractability issues that have prevented quality and variable markups analysis in the past.

From the first-order condition associated with Eq. (7), the optimal level of quality for a firm with productivity $\varphi$ is

$$q_{ij}(\varphi, \varepsilon) = \left( \hat{T}_{ij}w_{i} + w_{i}T_{ij}q_{ij}^{\eta} \right) \varepsilon / q_{ij}$$

(8)

and hence the quality adjusted marginal cost of supplying market $j$ from $i$ could be rewritten:

$$\tilde{c}_{ij}(\varphi, \varepsilon) = \frac{c_{ij}(\varphi, \varepsilon)}{q_{ij}(\varphi, \varepsilon)} = \left( \hat{T}_{ij}w_{i} / \eta w_{i}q_{ij}^{\eta} \right) \varepsilon / \eta w_{i}q_{ij}^{\eta} \varepsilon.$$  

(9)

It is immediate from this expression that more productive firms produce higher quality goods but actually face lower quality-adjusted costs. Also the quality-adjusted cost is an increasing geometric average of both types of shipping costs with the weights driven by $\eta$. As $\eta$ goes to one, specific trade costs matter not at all and our model becomes the model given by Jung et al. (2019). As $\eta$ goes to infinity, however, firm productivity becomes complete irrelevant and the weight of the specific trade cost goes to one. As a result, the more costly it is to upgrade quality (higher $\eta$) the less quality-adjusted marginal cost is decreasing in firm.
productivity within and across countries. Suppose the log case (i.e., $\sigma = 1$), the markup could be explicitly expressed as $\frac{1}{2\eta}$. As depicted in Panel D, the markup for a firm with the same productivity in high-income destination market should be higher since export productivity cutoff $\phi_{ij}^*$ is lower in high-income market.\footnote{Conditional on the same market, the distribution of markups should be the same because the term $\left(\frac{\varphi}{\varphi_{ij}(e)}\right)^{\frac{1}{\eta}}$ would follow a Pareto distribution with shape parameter equal to $\frac{1}{\eta}$. Hence, we compare the different markup across countries for the same firm instead of depicting the market distribution within each market.}

3.2.1. Discussion of alternative models

As we have just shown, our simple model that blends the “Washington Apples” mechanism with the variable markup framework of Jung et al. (2019) is capable of explaining all three empirical facts that appeared in Section 2. We now discuss the ability of more parsimonious models to confront these facts.

One branch of the literature extends the standard firm-heterogeneity model of Melitz (2003) by adding product quality differentiation (e.g., Johnson, 2012). These models can predict positive correlation between price and sales within a market across firms, but cannot explain the fact that firms set higher export prices in higher-income destinations and that more firms export to higher-income destinations. Moreover, they cannot confront the variation in markups across firms that has been documented by De Loocker and Warzynski (2012).

Another class of model features non-homothetic preferences and firm heterogeneity but lack endogenous quality (e.g., Jung et al., 2019). These models are well designed to confront the structure of observed markups across markets and perform well quantitatively along this dimension. In the absence of an endogenous quality mechanism, they cannot qualitatively match the observed positive correlation between price and sales within a market across firms or the fact that more productive firms charge higher prices within a given market.

Models that feature firm heterogeneity, endogenous quality, and variable markups are rare.\footnote{Feenstra and Romalis (2014) feature endogenous quality and variable markups but do so in an environment that lacks firm heterogeneity. Their analysis is not concerned with the across firm structure of prices and revenues.} A key exception is Antoniades (2015) who embeds endogenous quality into the model of Melitz-Ottaviano (Melitz and Ottaviano, 2008). As in Melitz and Ottaviano’s model, more productive firms charge higher markups but additionally can increase the quality of their output by incurring fixed innovation costs that rise in the quality of good produced. A unique feature of Antoniades’s model is that market size induces quality upgrading and so prices charged by firms in large markets should be higher as it is true in the data. While our model does not make this prediction regarding market size and prices, our model, unlike the Antoniades model, is consistent with the well-documented “Washington Apples” phenomenon. As the models differ in what facts they can explain, we choose to work with our relatively more parsimonious and highly tractable model. The Antoniades model is substantially more difficult to take to data because the endogenous quality choice mechanism generates firm level variables that are complicated functions of many model parameters and of endogenous aggregate variables.
3.3 Aggregation and equilibrium

In order to analytically solve the model and to derive stark predictions at the firm and aggregate levels, we follow much of the literature and assume that firm productivities are drawn from a Pareto distribution with cdf \( G_i(\varphi) = 1 - b_i \varphi^{-\beta_i} \) and pdf \( g_i(\varphi) = \beta_i b_i \varphi^{-\beta_i - 1} \), where shape parameter \( \beta > 1 \) and \( b_i > 0 \) summarizes the level of technology in country \( i \). We assume \( \varphi_i > b_i \) for all \( i,j \) so that the cutoff is active for all country pairs. The idiosyncratic cost shock \( \epsilon \) is drawn from a log normal distribution, where log follows the normal distribution with zero mean and variance \( \sigma^2 \).

We first derive the measure of the subset of entrants from \( i \) who surpass the productivity threshold \( \varphi_i(e) \) and so serve destination \( j \). The exporting firm mass from \( i \) to \( j \), \( N_{ij} \), is defined as

\[
N_{ij} = \int_0^\infty \Pr[\varphi - \varphi_i(e)] f(\epsilon) d\epsilon,
\]

where \( j \) is the potential firm mass in country \( i \) and \( f(\epsilon) \) is the pdf distribution of \( \epsilon \). The following simple expression of this mass of entrants can be obtained

\[
N_{ij} = \kappa J b_i \left( \varphi_i - \theta \right)^{-\beta_i - 1},
\]

(13)

where \( \kappa \) is a constant, and \( \varphi_i \) is the deterministic component of the productivity cutoff given by Eq. (12).\(^{14}\)

Note how the measure of entrants from \( i \) into market \( j \) depends on the “choke price,” \( \hat{p}_j \), through Eq. (12). An increase in the choke price induces a lower deterministic productivity cutoff and this expands the measure of firms operating there. The elasticity of the measure of active firms with respect to the choke price is \( \theta \eta_i \) and this illustrates how the “Washington Apples” effect interacts with the underlying productivity dispersion across firms.

We will see that all of the other aggregates in the economy are tightly linked to (13). In deriving these aggregates it is useful to define the conditional density function for the productivity of firms from \( i \) operating in \( j \) is

\[
\mu_i(\varphi, e) = \begin{cases} \theta [\varphi_i(e)]^{\beta_i - 1} & \text{if } \varphi - \varphi_i(e) \\ 0 & \text{otherwise.} \end{cases}
\]

(14)

With these definitions in mind, the aggregate price statistics, \( P_j \) and \( P_{j\alpha} \), can be rewritten as

\[
P_j = \sum_i N_{ij} \int_0^\infty \int_{\varphi_i(e)}^\infty \hat{p}_j(\varphi, e) \mu_i(\varphi, e) f(\epsilon) d\epsilon d\varphi,
\]

and

\[
P_{j\alpha} = \left[ \sum_i N_{ij} \int_0^\infty \int_{\varphi_i(e)}^\infty \hat{p}_j(\varphi, e)^{\alpha-1} \mu_i(\varphi, e) f(\epsilon) d\epsilon d\varphi \right] \frac{1}{1-\alpha}.
\]

As shown in Appendix C that contains detailed derivation for aggregate variables \( P_j, P_{j\alpha}, X_j \) and \( n_i \), all variation in prices due to the idiosyncratic trade cost shocks integrate out so that we may write these price statistics as

\[
P_j = \beta \hat{p}_j N_j,
\]

(15)

\[
P_{j\alpha} = \frac{1}{\beta \hat{p}_j} \hat{p}_j^\alpha N_j^\alpha,
\]

(16)

where \( N_j = \sum_i N_{ij} \) is the total mass of firms from all countries that have positive sales in country \( j \), and \( \beta \) and \( \beta_\alpha \) are constants that obtain after integrating out \( \epsilon \) from each expression (see Appendix C). Similar constants will also appear in each of the aggregate relationships displayed below.

We assume that there is free entry. Hence, in equilibrium, the expected profit of an entrant is zero and aggregate profits obtained by individual consumer are also zero. As a result, the representative consumer’s income \( y_i \) reduces to the wage rate \( w_i \) since each consumer has a unit of labor endowment. Then we have \( \hat{p}_j^* = \left( \frac{w_i + \pi_j}{X_j} \right)^2 \). The expression of \( \hat{p}_j^* \), together with Eqs. (15) and (16), imply that the quality-adjusted choke price is

\[
\hat{p}_j^* = \frac{1}{\beta \hat{p}_j} \frac{w_j}{N_j}
\]

(17)

Importantly, an increase in the per capita income in a country, \( w_i \), is associated with a greater choke price, while an increase in competition, \( N_j \), is associated with a lower quality-adjusted choke price.

Having derived expressions for the “choke price” and the price indices, it is straightforward to show that the total expenditure of country \( j \) on the goods from country \( i \), given by

\[
X_j = N_{ij} \int_0^\infty \int_{\varphi_i(e)}^\infty r_j(\varphi, e) \mu_i(\varphi, e) f(\epsilon) d\epsilon d\varphi,
\]

(18)

where \( X_j = w_j L_j \) is total absorption. Eq. (18) shows that our model shares with many commonly used models in the literature the feature that variation in trade volumes across country occur entirely along the extensive margin.

The expected profits can be calculated using

\[
n_i = \sum_j \int_0^\infty \int_{\varphi_i(e)}^\infty \pi_j(\varphi, e) \mu_i(\varphi, e) f(\epsilon) d\epsilon d\varphi.
\]

As shown in the appendix, these expected profits can be shown to be

\[
n_i = \frac{1}{\beta} \frac{\beta_\alpha}{\beta_\alpha - \beta} \frac{X_j}{N_j^\alpha},
\]

(19)

where \( \beta_\alpha \) is also a constant.\(^{15}\)

The household budget equation implies that total income equals to total expenditure

\[
w_i L_i = \sum_j X_j
\]

(20)

Free entry, \( n_i = w_iL_i \) together with (18), (19), and (20) pin down the measure of entrants:

\[
f_i = \frac{\beta_\alpha}{\beta_\alpha - \beta} \frac{L_i}{X_j}
\]

(21)

So, as in standard models of monopolistic competition in the Krugman tradition, the measure of entrants is proportional to country size and invariant to the trading environment. Finally, we assume trade is balanced:

\[^{14}\kappa = \int_0^\infty e^{-\varphi_{1i} \sigma} f(\epsilon) d\epsilon = \exp\left\{ \frac{1}{2} (1 - \eta) \theta \sigma^2 - \theta \right\} \].

\[^{15}\text{Notice here we have that firms' total variable profit is proportional to total revenue as Arkolakis et al. (2012).} \]
\[
\sum_j X_{ij} = \sum_j X_{ji}, \quad (22)
\]

This concludes our characterization of the equilibrium. Note that Eqs. (12), (13), and (18) imply the following theoretical gravity relationship:

\[
\frac{\lambda_y}{\lambda_y} = \frac{J_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}}{f_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}} \quad (23)
\]

Eq. (23) will lead to an empirical gravity equation for estimation in the later calibration.

4. Quantification

This section describes how we solve, calibrate and simulate our benchmark model. We first estimate the parameters of the benchmark model. There are two sets of parameters. The first set \( \Theta_1 = \{ \eta, \theta, \tau, \sigma^2, \} \), including the inverse of quality scope, the productivity shape, the standard deviation of specific trade cost shocks, and the elasticity of substitution. The second set \( \Theta_2 = \{ \{ w_i, p_{w_i}, b_i, b_j, \tau_{ij}, b_{ij} \}_i \}_j \} \) includes all endogenous macro variables.\(^{16}\) We show that our model specification enables us to identify \( \Theta_1 \) without information about \( \Theta_2 \). Therefore, we can first identify \( \Theta_1 \) and then recover macro level parameters in \( \Theta_2 \) through the structural equations implied by the model. We then simulate the model based on parameter estimations.

4.1. Parameterization

In this subsection, we first show how a gravity equation can be used to recover an important model parameter. Next, we show how the remaining parameters in the set \( \Theta_1 \) can be recovered. Finally, we show that given estimates of the parameters in \( \Theta_1 \), the model’s structural equations can be used to recover the parameters in \( \Theta_2 \).

4.1.1. Gravity and the two trade elasticities

The set \( \Theta_1 = \{ \eta, \theta, \sigma^2, \sigma^2 \} \) contains four key parameters of our model. We begin by discussing the estimation of \( \eta \). Following Caliendo and Parro (2015) and Arkolakis et al. (2018), we estimate \( \theta \) from the coefficient on tariffs in a gravity equation. Taking the logarithm of Eq. (23) yields an empirical gravity equation for estimation:

\[
\log \left( \frac{\lambda_y}{\lambda_y} \right) = \log \left( \frac{J_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}}{f_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}} \right) = \log \left[ \frac{J_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}}{f_J b_J \left( \tau_{ij}^{-1} \tau_{ij} \log w_j \right)^{\theta}} \right] + \theta \log T_{ij} - \theta \log \tau_{ij}, \quad (24)
\]

where \( S_i \) is the exporter fixed effect, and \( S_j \) is the importer fixed effect. We call the coefficient on \( \log \tau_{ij} \) the ad-valorem trade cost elasticity and the coefficient on \( \log T_{ij} \) the specific trade cost elasticity. Note that these coefficients are structural but identify different parameters.

To estimate a trade elasticity, we must make auxiliary assumptions. First, we assume that both \( \log T_{ij} \) and \( \log \tau_{ij} \) are linear in bilateral pair geography. Second, we assume that the majority of the tariff variation observed for manufactured goods are ad valorem, which is reasonable for manufactured goods.\(^{17}\) Following Waugh (2010) and Jung et al. (2019), we use a set of gravity variables to proxy for \( T_{ij} \) and for \( \tau_{ij} \) through the following equations:

\[
(\eta-1) \log(T_{ij}) = c_0 + \log \left( \frac{\lambda_y}{\lambda_y} \right) \quad (25)
\]

where \( c_0 \) is assumed to be Gaussian measurement error. Note how the coefficient on tariffs, the ad valorem trade cost elasticity, has a structural interpretation. It is the productivity distribution shape parameter \( \theta \). Further, also note that with an estimate of \( \theta \) it becomes possible to back out from these estimates the aggregate trade cost \( (T_{ij})^{\theta-1} \).

The bilateral trade share \( \lambda_y \) is constructed following the method in Ossa (2014) by using the GTAP 9 data for the year 2004.\(^{18}\) Bilateral gravity variables: \( \text{dist}_{ij}, \text{d}_{ij} \) (common currency, common official language) is taken from the CEPII dataset. The tariff data is from WITS, where we compute the average tariff rate for all HS8 sectors of each destination to represent \( \text{tar}_{ij} \).\(^{19}\) We let \( \text{tar}_{ij} = 1 \) if \( \text{trade} \) is internal. We also let \( \text{tar}_{ij} = 1 \) if both \( i \) and \( j \) belongs to EU, NAFTA, ASEAN members countries. For the case of EU, we apply common external tariff by the EU for non-EU members. The summary statistics are presented in Table 4.

The coefficients on the gravity variables and tariffs obtained by estimating Eq. (25) via OLS are shown in Table 5. The estimates on the standard gravity variables all of their expected sign and fall in common ranges for gravity equations (see Head and Mayer, 2014). For instance, a 10% increase in distance is associated with an approximately 7.65% reduction in the volume of trade. Most importantly, the coefficient of \( 6.1 \) on \( \text{tar} \) is sensible and is measured with high precision.\(^{20}\) We now discuss the estimation of the model’s other key parameters.

4.1.2. The remaining parameters of \( \Theta_1 \)

Our approach to estimating the remaining coefficients is very different. To identify the idiosyncratic dispersion in trade costs, \( \sigma^2 \), the taste parameter \( \sigma^2 \), and the quality upgrading cost elasticity \( \eta \), we make use of our estimate of \( \theta \), the model, and moments from firm-country-product data on unit values \( (p_{ij} \alpha) \) in the model) and export values \( (r_{ij} \alpha) \) in the model). The core of our estimation strategy involves using the first-order condition for price determination \( (6) \) and values of \( \sigma^2, \sigma^2, \eta \) to generate an artificial dataset that match the standard deviation of the logarithm of price charged by Chinese firms, the standard deviation of the logarithm of the corresponding sales, and the correlation of the logarithm of prices with the logarithm of sales.

We follow the simulated method of moments procedure in Eaton et al. (2011) and Jung et al. (2019). In particular, we define \( u = b \sigma q \alpha \).

\(^{15}\) In our calibration, we focus on 36 countries, i.e., \( l = 36 \).

\(^{16}\) Strictly speaking tariffs are not standard cost shifters like shipping costs, but we follow much of the literature in assuming that they are. For a discussion see Costinot and Rodriguez-Clare (2014) and Felbermayr et al. (2013).

\(^{17}\) The bilateral trade shares \( \lambda_y \) are only constructed for our selected 36 countries. For any \( i \neq j \), we first compute \( X_{ij} \) as the sum of trade flow from \( i \) to \( j \) across all GTAP sectors. We then compute \( X_{ij} = X_{ij}^0 + \sum X_{ij}^0 \). We then compute \( X_{ij}^0 = X_{ij}^0 / \sum X_{ij}^0 \). One important advantage of using GTAP is that we do not get missing-negative value for our constructed \( X_{ij} \) and hence all the values for \( \lambda_{ij} \) are valid.

\(^{19}\) The year 2004 tariff data for Russia is not available. We use the year 2005 instead. We also try year 2002 as an alternative, the result is very similar.

\(^{20}\) This number falls in the range of estimates in Arkolakis et al. (2018).
where \( b \) denotes China’s productivity. The cumulative distribution of \( u \) can be shown as follows

\[
\Pr(U = u) = \Pr(b \varphi^{-1} u) = \Pr\left(\varphi^{-1} \left( \frac{b}{u} \right) \frac{1}{\bar{u}} \right) = u.
\]

The conditional productivity entry cutoff \( \varphi_u(\epsilon) \) can also be written in terms of \( u \),

\[
u_u(\epsilon) = b_u \left[ \frac{\eta_u \Gamma(1-\eta_u)}{\Gamma(1-\epsilon_u)} \right] \left( \frac{1}{\bar{u}} \right) \exp\left( -\frac{\epsilon_u}{\sigma_u} \right) \varphi_u(\epsilon).
\]

Eq. (26) implies that a firm that has received cost shock \( \epsilon \) will export when \( u < u_u(\epsilon) \). Importantly, \( \bar{u} = \frac{u}{u_u(\epsilon)} \) follows a uniform distribution from \([0,1]\) where the highly efficient firms with \( \bar{u} \) close to zero and the marginal firms with \( \bar{u} \) close to 1. We first draw 1,000,000 realizations of \( u \) from uniform distribution on \([0,1]\). Each draw corresponds to a simulated exporter. For each exporter, we draw \( 1 (=36) \) destination specific realizations of \( \bar{u} \) from the standard normal distribution. Note that by construction, \( \bar{u} = \left( \frac{\varphi_u(\epsilon)}{\varphi_u(\epsilon_u)} \right) \) and \( \bar{\epsilon} = \frac{1}{\sigma_u} \log(\varphi_u(\epsilon)) \), thus the true productivity \( \varphi \) and the real cost draw \( \epsilon \) can be recovered whenever necessary.

Combining Eqs. (9)–(11) with (6), yields the following expression:

\[
\alpha_u = \left( \frac{p_j(u)}{p_j} \right)^{\alpha - 1} \left( \frac{p_j(u)}{p_j} \right)^{\alpha - 1} \bar{u}. \tag{27}
\]

Note that the inverse of the left hand side follows a Pareto distribution with location parameter 1 and shape parameter \( \alpha_p \). We can recover \( \bar{p}_j = \frac{p_j(u)}{p_j} \) according to the previous equation for each \( \bar{u} \). To connect the implied pricing behavior in the model with the Chinese firm-product-country data, we define the following transformation:

\[
p_j(u, \bar{u}, \bar{e}) = \frac{p_j(u)}{p_j} \left( \frac{c_i(\bar{e})}{c_j(\bar{e})} \right) \frac{p_j}{p_j(\bar{e})},
\]

where \( c_i(\bar{e}) = \frac{\eta}{\eta - 1} \omega T y \exp(\sigma_c \bar{e}) \) is the endogenous (unadjusted) marginal cost of firms. Using Eqs. (9) and (11) and taking logarithms yields

\[
\log p_j(u, \bar{u}, \bar{e}) = \log \left( \frac{p_j(u)}{p_j} \right) + \sigma_c \bar{e} - \frac{1}{\eta} \log(\bar{u}) + \log \left( \frac{\eta}{\eta - 1} \omega T y \right). \tag{28}
\]

This implies that the standard deviation of log export price, once we subtract the destination average to eliminate the constant term (the last term on the right), will only depend on the parameter set \( \Theta_1 = \{ \eta, \theta, \sigma_c, \sigma_e \} \), and is not destination specific.

Making similar transformations for the logarithm of the sales revenue of a firm, given by (4), we obtain:

\[
\log g_j(u, \bar{u}, \bar{e}) = \log \left( \frac{g_j(u)}{g_j} \right) + \sigma_c \bar{e} - \frac{1}{\eta} \log(\bar{u}) + \log \left( \frac{\eta}{\eta - 1} \omega T y \right). \tag{29}
\]

This expression shows that the standard deviation of country-product exports by Chinese firms, once it has been demeaned by subtracting its sector-destination mean, depends only on parameters \( \eta \) and \( \sigma_c \). Notice that two types of relationships here are relevant. First, both parameters drive the standard deviation of \( \log g_j(u) \), while only \( \sigma_c \) governs the dependence of \( \log g_j(u) \) on \( \bar{p}_j(\bar{u})/\bar{p}_j \). Moreover, we can obtain the correlation between log-sales and log-price given parameters \( \eta, \sigma_c, \) and \( \sigma_e \). Our discussion suggests that these three moments are sufficient to jointly identify our three parameters \( \eta, \sigma_c, \) and \( \sigma_e \) via simulated Generalized Method of Moments, while our gravity estimate of \( \theta \) allows us to separate \( \eta \) from \( \Theta_e \).

We now summarize the estimation strategy. First, we calibrate \( \sigma_e \) to target the standard deviation of the log of export sales. To see this, notice that in Eq. (29), \( \bar{p}_j(\bar{u})/\bar{p}_j \) is bounded from 0 to 1 (the marginal exporter to destination \( j \) takes value 1 while for the most productive firms it tends toward 0). An increase in \( \sigma_e \) makes sales more responsive to productivity and so leads to larger sales dispersion. Second, we choose \( c_i \) to target the standard deviation of the log of export price. Firms’ marginal cost depends on the trade cost draw \( \bar{e} \) (see Eq. (28)), so greater dispersion of these shocks yields greater dispersion of price. Third, the correlation between log-sale and log-price helps to identify \( \sigma_c \). In a model without quality, as in Jung et al. (2019), price and sales exhibit negative relationship because the productive firms have lower marginal cost. This negative relationship is overturned here because high productivity firms produce higher quality which allows firms to raise their prices. This mechanism can also be seen from the \( \log g_j(u) \) term in Eq. (28): a lower \( \bar{u} \) implies a higher real efficiency and hence higher price and sales. The distribution of \( \bar{u} \) is governed by the value of \( \sigma_e \).

To construct the three micro moments for the data, we use the Chinese customs’ ordinary trade data at the year 2004. We aggregate the data into firm-country-HS6 level, construct our data moments for by each country-HS6 pair and choose the median among them. The parameters are jointly identified through the following minimization routine:

\[
\min_{\eta, \theta, \sigma_c, \sigma_e} \left\{ \left( m^D - m^M(\eta, \theta, \sigma_c, \sigma_e) \right)^T W \left( m^D - m^M(\eta, \theta, \sigma_c, \sigma_e) \right) \right\}
\]

where \( m^D \) is the (column) vector that contains the data moments, and \( m^M(\eta, \theta, \sigma_c, \sigma_e) \) contains the corresponding model moments. \( W \) is identity weighting matrix.

Following Jung et al. (2019), we check the sensitivity of our quantitative results by comparing the estimates from our exactly identified
4.1.3. Solving for $\Theta_2$

The set of $\Theta_2$ includes all endogenous macro variables. We begin by describing how we uncover wages, the measure of total entrants per market, and aggregate prices statistics.

To solve wage $w_i$ for each country, we use the labor market clearing condition, which is given by

$$w_iL_i = \sum_j X_{ij} = \sum_j \lambda_j w_j L_j.$$  

Here we normalize the wage in US to be 1 so that every other country’s wages are all relative to the US. Market size $L_i$ is proxied by total population of that country, which is from the CEPII dataset. Note that market size immediately pins down the number of entrants per country, $B_i$, from Eq. (21).

To recover $b_j$, we use the importer fixed effect from the gravity estimation in Eq. (23) which is

$$S_j = \log \left( \left( B_j \right) \left( w_j \right)^{-\eta \phi} \right),$$

where $S_j$ is the estimated importer fixed effect.\(^{21}\) The bilateral trade cost ($T_j^{-1} \tau_j$) can also be recovered from the gravity Eq. (23).\(^{22}\) Finally, we solve for the mass of firms that serve country $j$, $N_j$, using Eqs. (13) and (17). These two equations when combined yield

$$N_j = \frac{\eta - 1}{\eta + 1} \left( T_j^{-1} \tau_j \right)^{-\frac{1}{\eta - 1}} w_j \left( \frac{N_j \phi}{\lambda_j w_j} \right)^{-\frac{1}{\eta}}.$$  

Having recovered all the variables in this expression up to the constants, we can use Chinese customs data to compute the total number of firms that export from China to country $j$, $N_{\text{China}, j}$, except for China itself. Then $N_j$ ($j = \text{China}$) can be computed from the above equation.

4.2. Model simulation

Given estimates for all the key parameters, we can simulate the model to assess its ability to reproduce the facts that were illuminated in Section 2. We follow the procedures below to construct the full model.

(1) For each draw of $\hat{u}$, we construct entry hurdles $u_j^\prime(\hat{u})$ for each country $j$ using Eq. (26).

(2) For each $\hat{u}$, we compute $u_j^\prime(\hat{u}) = \max_{j \neq \text{China}} \{ w_j(\hat{u}) \}$. This is the minimum requirement productivity for a firm to sell its product in countries other than China. We then construct $u = u_j^\prime(\hat{u})$ using our draw of $\hat{u}$ in step (1). Because in the model, the measure of firms that export from China to country $j$ is $u_j^\prime(\hat{u})$, our artificial exporter $u$ is assigned a sampling weight of $u_j^\prime(\hat{u})$.

(3) For each $u$, we set the export status $\delta_j$ indicating whether firm $u$ exports to $j$ to be given by

\[ \delta_j(u) = \begin{cases} 1, & \text{if } u \leq u_j^\prime(\hat{u}) \\ 0, & \text{otherwise} \end{cases} \]

(4) We recover firm level variables, which include productivity, price and sales. First, we obtain firm level productivity from $\varphi = \left( \frac{b_j}{u} \right)^{\frac{1}{\eta}}$.

Second, we construct exporter-destination quality $q_j(\varphi, \epsilon)$

$$q_j(\varphi, \epsilon) = \left( \frac{\varphi \cdot T_j^{-\frac{1}{\eta}} \tau_j^{-\frac{1}{\eta - 1}}}{} \right)^{\frac{1}{\eta}}.$$  

Note that at this juncture, we have to take a stand on the relative magnitudes and cross-country variation in $T_j$ and $\tau_j$. Motivated by the discussion in Hummels and Skiba (2004), we assume that $T_j$ specific costs account for all of the geographic variation in the gravity equation and $\tau_j$ is driven exclusively by tariffs. Finally, we compute firm-level prices that are not adjusted for quality:

$$p_{ij}(\hat{u}, \hat{e}) = \frac{\hat{p}_{ij}(\hat{u}, \hat{e})}{\hat{p}_{ij}} = \frac{\hat{p}_{ij}(\hat{u}, \hat{e})}{\hat{p}_{ij} \cdot q_j(\hat{u}, \hat{e}),}$$

where $\hat{p}_{ij}(\hat{u}, \hat{e})$ are solved through the pricing Eq. (27). Finally, firm sales can be constructed from Eq. (4).

In summary, after dropping non-exporting Chinese firms, we have constructed a dataset that contains one million exporting firms that can export to a maximum of $(I - 1)$ countries. We now turn to the estimation results and the assessment of model fit.

5. Results

In this section, we begin with the benchmark model by reporting the parameter estimates for $\Theta_1$ for both the exactly identified and the over identified cases. We then report summary statistics for our estimates of the parameters in $\Theta_2$ calculated using the exactly identified parameters in $\Theta_1$ and generate pseudo-Chinese exporters that is comparable with the customs data to evaluate the model fit by comparing the real data and model simulated data. We conclude the section by presenting the welfare results of our model.

5.1. Model fit

We begin with our estimates of the parameters of the benchmark model which are shown in the following table. Table 6 lists our calibration results for the key set of parameters $\Theta_1$, and shows that the parameter estimates obtained under both exact identification and over identification strategies are similar. As in Jung et al. (2019), when we try to match the tails of the sales and prices distribution in the over identification case, $\sigma$ increases to match the large dispersion in the firm-level data. Compared with the exact-identified case, the over-identified model slightly overpredicts the dispersion of firm sales and prices.

\(^{21}\) In the above regression, we’ve added both the importer and exporter fixed effect. This induces multi-collinearity. To avoid this, we follow Levchenko and Zhang (2016) and normalize the importer fixed effect $S_i$ for US to 0. Essentially, we choose US for the reference country, and the importer fixed effect estimates for all other countries are all relative to the reference country.  
\(^{22}\) Note that we set $T_j^{-\frac{1}{\eta}} \tau_j = 1$ for all $j$.  

Table 6 Calibration of $\Theta_1$
Table 7 further presents the data targets and the simulation results for both targeted moments (see Panel A) and non-targeted moments (see Panel B). Given the trade elasticity, our model matches the targeted moments relatively well although it underestimates the extreme skewness in firm sales and overestimates the skewness in firm prices. Our non-targeted moments are exporter sales advantage, measured as the ratio of domestic sales of exporters to non-exporters, and exporters’ export intensity measured as the share of output that is exported. There are three measures of export intensity: the share of firms that export less than 10% of their total revenue, the share of firms that export between 10 and 50% of their output, and the share of firms that export more than 50% of their output. All non-targetted moments were computed using a merged sample between customs data and the NBSC manufacturing survey data. Here, we see that the overidentified specification does a better job fitting the export intensity distribution than the exactly identified model.

The markup distribution formula in our model is the same as in Jung et al. (2019). Yet, we fit to different moments and different parameter values are obtained. Thus, our model’s generated markup distributions have a relatively thin tail than those in Jung et al. (2019). Our estimate of the elasticity of substitution implies that the upper bound for markups would be \( \epsilon = 1.26 \). Given that \( \theta = 6 \), the model’s generated markups distribution has a relative thin-tail. Thus, the average markup charged by exporters in our model is lower than that of Jung et al. (2019). More specifically, our model implied average markup is 1.0229, the log(markups) 99–50 percentile ratio is 0.0853, and the log of markups 90–50 is 0.0517. We plot the model simulated markups and sales distribution in Fig. A.1 in Appendix E.

We now check the model’s fit for the solution to our model. The four panels of Fig. 5 demonstrate the fit of our model to data. The first panel shows that the logarithm of the wage by country relative to country averages implied by the model closely follows the logarithm of GDP per capita relative to country averages as reported in the CEPII data set, explaining over 80% of the variation in cross country incomes. In the second panel, we plot the implied productivity by country versus its GDP per capita. This too shows a very strong fit. In the third panel, we plot model generated specific trade costs against the real data of distance from China to each destination country and observe a very strong positive slope. In the last panel is the number of Chinese firms that serve a particular country predicted by the model against the actual number of entrants. Our model’s predictions closely mirror the variation across countries in terms of the extensive margin.

We now turn our attention to the key object of interest in our paper, the relationship between the price charged by a firm and its sales. Fig. 6 illustrates the price and sales relationship for both data and model. For the data, we first construct firm’s normalized sales by subtracting each firm’s log sales by its HS6×destination average. We apply the same treatment for the firm’s price. Then, for each HS6×destination pair, we sort firms’ normalized sales into 10 deciles. In this step, we require that each HS6×destination have at least 10 firms so that the 10 deciles can be properly obtained. We then compute the median of both the normalized price and sales at each decile for each HS6×destination pair. We finally aggregate the median value for all HS6×destination pairs, leaving only one value for each sales decile. For the model, we follow a similar procedure. Thus, each dot in the figure represents deviations of log sales from their relevant industry mean relative to the deviations of log price from their relevant industry mean.\(^{23}\)

Quantitatively, the model traces the data reasonably well. In the data, when log firm sales increase from \(-3\) to \(+3\), the logarithm of the firm price increases by 0.25, whereas in the model, it increases by about 0.15. Hence, the model explains about 60% of the positive relationship between price and sales. The increase for the model mostly comes from large firms, i.e. firms that have higher sales than average. For the small firms, the model predicts a higher price level than that of the data. The reason appears to stem from the endogenous cut-off price induced by non-homothetic preferences that limit the scope for variation among small firms.

Note that the positive relationship between prices and sales in Fig. 6 also highlights the importance of the interaction of variable markups and endogenous quality. This is because, with endogenous quality under monopolistic competition, variable markups as in Jung et al. (2019) are essential for our model, which aims to reconcile the price dispersion across firms and across markets, to generate positive relationship between sales and prices. If firms were to set constant markups over marginal costs, there would be no correlation between firms’ sales and prices which can be seen from the marginal cost formula \( \bar{c}_q(\tilde{e}) = \frac{n}{\eta - 1} \bar{w}_T \sigma e^{\sigma x \tilde{e}} \). In other words, the variable markup mechanism is crucial for our model that features both endogenous quality and pricing-to-market to deliver factual relationship of prices and sales. On the other front, there are existing studies that rely on the quality mechanism alone to generate this positive relationship, such as Johnson (2012), but these endogenous-quality models are not able to explain the facts across countries that firms set higher export prices in higher-income destinations and that more firms export to higher-income destinations. Our model is to generate exporter pricing pattern both within market and across markets in a unified general equilibrium framework.

Next we consider the model fit along dimensions not directly fit in our calibration procedure. We first consider the within and across firm variation in prices as a function of the GDP per capita of the destination country. Fig. 7 shows this relationship for the model in the left-hand panels and in the data in the right hand panels. The top two panels are the variation across country within firms (intensive margin) and the middle two panels are the relationships averaged across all firms (intensive and extensive margin). The model predicts a slightly stronger correlation between price and GDP per capita than the data but slightly less variation than the average across all firms. Both deviations can be understood with respect to the price-revenue relationship shown in

Notes: The targeted moments are constructed from customs data, which covers the universe of all exporters and importers. The non-targeted moments are constructed from the merged sample based on customs data and Chinese Manufacturing Survey data provided by NBS (National Bureau of Statistics of China), because we need both exporters and non-exporters in the non-targeted moments to check exporter domestic sales advantage, and we also need total sales information from the NBSC data to compute export intensity.
Fig. 6. Looking at only the intensive margin disproportionately picks up firms in the higher end of the productivity distribution that have high prices and high revenue, while the average price that includes the extensive margin picks up the small firms whose behavior the model has trouble fitting.

We now look more closely at the extensive margin in Fig. 7. The panel E is the model prediction of the measure of entrants as a function of country per capita income while the panel F is the actual data. The model correctly predicts a positive relationship between the two, but there is slightly less variation in the model predictions than there is in the data. In addition, we also check the relationship between firm sales, prices and quality with market size (measured by the product of population and wage) and plot those positive relationships simulated by the model in Fig. A.2 in Appendix E.

5.2. Welfare discussion

In this section we show how the gains from trade are related to the key parameters of the model. Following the Equivalent Variation approach (i.e., the welfare formula is derived by total differentiating the expenditure function), we derive a (local) welfare formula of our benchmark model inspired by Arkolakis et al. (2019). The change in welfare associated with a small trade shock in country \( j \) can be derived as follows (see online appendix D for the derivation):

\[
d \ln W_j = - \left(1 - \frac{\rho}{1 + \eta \theta}\right) \frac{d \ln \lambda_{ij}}{\eta \theta},
\]

where \( \rho \) is the average markup elasticity and is defined by

\[
\rho = \int_1^\infty \frac{d \ln \mu}{d \ln v} \left[ \frac{\mu v^{-1} (\mu^{-\sigma} v^{\sigma-1}) v^{-\sigma-1}}{\mu v^{-1} (\mu^{-\sigma} v^{\sigma-1}) v^{-\sigma-1}} \right] dv,
\]

where \( v = \left(\frac{\nu}{\rho_{ij}}\right)^{\frac{1}{\sigma - 1}} \) measures the inverse of quality adjusted marginal cost, and \( \mu \in [1, \frac{\sigma}{\sigma - 1}] \) is the corresponding markup component that satisfies the following pricing equation

\[
\frac{\sigma}{v} = (\mu v^{-1})^{\sigma + 1} + (\sigma - 1) (\mu v^{-1}).
\]

Eq. (30) show that the key parameters for assessing welfare implications of shocks are the parameter \( \rho \) which captures the markup elasticity, \( \theta \) which governs the degree of dispersion in productivity, and \( \eta \) which governs the cost of quality upgrading in the model. Here
Eq. (30) computes a local measure of welfare gains under a small change in trade shocks as in Arkolakis et al. (2019). As in Arkolakis et al. (2019), the welfare gains should be lower than that under the case with the constant markup. Note that in Eq. (30) the markup pass-through parameter $\rho$ is a function of $\eta \theta$. This is because, in Eq. (31), the quality adjusted marginal cost, $1/v$, follows a Pareto distribution with shape parameter $\eta \theta$. Given taste parameter $\sigma$, this implies the markup pass-through parameter $\rho$ depend only on $\eta \theta$. As $\eta \theta$ sufficient to compute gains from trade, the role of quality in accessing welfare gains relies on how we estimate $\eta \theta$ (the true trade elasticity of our model), and is therefore quantitative. Here, the distinction between the specific trade cost elasticity and the ad-valorem trade cost elasticity is important. For instance, if we were to set $\tau_j = T_j$, we would obtain the true trade elasticity with respect to trade costs is $\eta \theta$ in the models with endogenous quality. Based on Eq. (31), given the calibrated parameter values in Table 6 (the exact-

---

Fig. 7. Model fit: price-wage relationship and entrants-wage relationship. Notes: In the top two panels, we normalize each exporter’s price by it’s price at USA $(\log p_{\text{CHN},j}(\phi, \epsilon)/p_{\text{CHN},\text{US}}(\phi, \epsilon))$, we then calculate the average destination price as the mean of this normalized price across firms on each destination. For the bottom two panels, we calculate the average destination price as the simple average of log price for all exporters on that destination. For the model, $w_j$ is model predicted wage rate; for the data, $w_j$ is the 2004 destination GDP per capita in CEPII. For consistency with our empirical exercise, we control for log destination population, and log distance for both the data and the model. Since the model does not have an exact counterpart for distance, we thus use $T_{ij}$ as a proxy.

---

24 For the comparison between global versus local welfare, please see a comprehensive discussion in Bertoletti et al. (2018).

25 Were we to strip the model of its “Washington Apples” mechanism, the model would be essentially identical to Jung et al. (2019). In that case, the coefficient on the change in the domestic consumption share in the welfare formula becomes $-\frac{1 - \rho \eta \theta}{1 + \theta \theta}$.

26 Note that the above results are obtained by assuming tariff to act as cost shifters and using tariff to measure trade elasticity. However, as discussed briefly in Costinot and Rodríguez-Clare (2014) and Felbermayr et al. (2013), tariffs could also be viewed as revenue shifters which would lead to a different estimation of trade elasticity instead of viewing tariffs as iceberg trade costs.
identification results), we compute the markup pass-through elasticity $\rho = 0.37$ in our benchmark model which is consistent with Jung et al. (2019), who analytically show $\rho \in (0.05)$ for GCEGs models. Then we can compute welfare gains for all countries. We now turn to a comparative static that also highlights the complications that arise in models with ad-valorem trade costs, specific trade costs, and endogenous quality upgrading.

6. Comparative static

In this section we show that the impact of trade cost shocks on prices depends crucially on the nature of the shock. Consider a 5% increase in trade costs between country $i$ and $j$ as measured by $T_{ij}^{-1} \tau_{ij}$. Whether this increase was due to an increase in $T_{ij}^{-1} \tau_{ij}$ or some mixture of the two has no bearing on welfare or trade volume effects of the liberalization. As shown in this section, there are very big differences in the effect of these trade liberalizations on prices. Intuitively, an increase in $T_{ij}^{-1} \tau_{ij}$ raises the cost of serving the market and induces quality upgrading which leads to higher prices, whereas an increase in $\tau_{ij}$ induces firms to reduce their quality. Combined with the extensive margin effect through a change in firm productivity cutoff after increases in trade costs, the overall effects on average export prices are different for two types of trade costs.

In this section we demonstrate how these shocks lead to changes in prices quantitatively and then contrast the price effects of a 5% increase in ad valorem trade cost with an equivalent increase in specific trade cost. In addition, we check the effect of two types of trade costs shock on the distributional moments of prices, sales, and markups.

Applying “hat” algebra to the choke price $p_C$ and Eqs. (12) and (13), it is straightforward to solve $p_C$ and $\varphi_C$ according to the following two equations:

$$p_C = \frac{\tilde{w}_j}{\sum_i \tilde{w}_i (\varphi_C)}$$

(32)

$$\varphi_C = T_{ij}^{-1} \tau_{ij} (\tilde{w}_j)^T (\tilde{p}_j)^{-1}$$

(33)

where $\tilde{w}_j$ can be solved endogenously from the model. We can obtain other macro variables in a similar way by applying the hat algebra.

Next, we re-simulate the model to generate pseudo exporters using our solved macro variables after the trade shock. We use the same firm productivity draw ($\varphi$) and cost shock draw ($\varepsilon$) in the benchmark simulation. This guarantees that our comparative statics are performed on the same set of firms and cost draws, and all the changes are solely driven by the change in $T_{ij}$ or the change in $\tau_{ij}$. Specifically, for a firm with productivity $\varphi$ and cost draw $\varepsilon$, we construct after-shock firm price using

$$(\tilde{p}_{CHN}, (\varphi, \varepsilon))' = \left(\frac{\tilde{p}_{CHN,j}(\varphi, \varepsilon)}{p_j}\right)' \left(\frac{\varphi_{CHN,j}(\varphi, \varepsilon)}{p_j}\right)'$$

where $\left(\frac{\tilde{p}_{CHN,j}(\varphi, \varepsilon)}{p_j}\right)'$ depends on $(\varphi'/\varphi_{CHN,j}(\varphi, \varepsilon))'$ via the firm pricing Eq. (27) and where $(\varphi_{CHN,j}(\varphi, \varepsilon))' = (\varphi_{CHN,j}(\varphi, \varepsilon))' \varepsilon^{-1}$ denotes the after-shock productivity cut-off. Similarly, $(\tilde{p}_j')' - \tilde{p}_j p_j$ is the after-shock quality adjusted choke price and $(\varphi_{CHN,j}(\varphi, \varepsilon))'$ is the after-shock optimal quality choice. Finally, we compute the mean of log-price across firms for each destination.

Fig. 8 shows the results of our comparative static. The top panel shows the impact of $T_{ij}^{-1} = 1.05$ for $i \neq j$ on average export prices set by our model simulated Chinese firms across countries in our data set while the bottom panel shows the results across the same set of countries for $\tau_{ij} = 1.05$ for $i \neq j$.

The differences in the results are both striking and intuitive. On average a 5% increase in specific trade costs induces an approximately 6.5% increase in export prices as the shock both raises the cost of serving the market and induces firms to upgrade their quality. The increase in firm productivity cutoff magnifies this latter effect so that there appears to be more than 100% pass through. For the case of a shock to ad valorem trade costs, the effect on average is very close to zero because there are competing effects of roughly equal magnitude. On the one hand, higher ad valorem trade costs induce firms to downgrade their quality and so reduce their prices. On the other hand, higher ad valorem trade costs raise the firm productivity cutoff which induces weaker firms to exit and thus increase average prices. These two effect offset each other so the overall effects of ad valorem trade costs on export prices are small.

If firms set constant markups over marginal costs, the ad valorem trade costs would not affect the price, and hence the effect on export prices is only from the changes in specific trade costs. After introducing variable markups, the ad valorem trade costs would affect both productivity cutoff and prices. However, its impact of ad valorem trade costs on prices is still smaller compared to the impact of specific trade costs on prices.

The key point to take away from this comparative static is that when trade costs are a mixture of ad valorem and specific as must be so in the real world, the relationship between import prices, export volumes, and the gains from trade becomes complicated. The nature of the shock determines this relationship.

Finally, we examine the effect of different trade costs on distributions of prices, sales, and markups in different destinations in Table 8. We focus on the same set of firms that export to the specific destination before and after the trade cost shock and find the following observations. First, due to the quality mechanism, price levels change differently depending on trade shocks from $T$ or $\tau$, which can be seen from the mean of log prices in panels A and B. Second, only the price levels show differential responses to $T$ and $\tau$ shocks. The other variables – including the dispersion moments of prices, markups, and sales, the levels of markups and sales, as well as the correlations between prices, markups, and sales – display identical changes in response to either $T$ shock or $\tau$ shock. This is because the two types of trade cost shocks have identical effect on productivity cut-off $\varphi_C(\varepsilon)$ by construction. We report those common responses of various distributional moments to $T$ and $\tau$ shocks in Panel C.

It is interesting to note that after the trade cost shock, the dispersion of prices alters very little, while the dispersion of sales changes substantially. This is because high- versus low-productivity firms show differential responses to trade cost shocks. To demonstrate the mechanism at work, we illustrate the changes in prices and sales by a low- versus high-productivity firm that exports to destination $j$ using Fig. A.3 (see Appendix E for details). The analytical result of the illustration in Fig. A.3 suggests that firms with different initial productivities change their export prices to a similar extent, whereas the associated changes in their sales are profoundly asymmetric across firms, with relatively less productive firms reducing their sales by more. As a result, we

---

27 The exact steps are omitted here to save space.

28 In our model, $\tilde{w}_j$ is implicitly given by,

$\tilde{w}_j = \sum_i \tilde{w}_i (\tilde{p}_j)$

29 Due to an increase in $\varphi_{CHN,j}$, some unproductive firms that use to export to destination $j$ before the shock will not be able to export after the shock.

30 See, for example, for Canada, under a cost shock of a 5% increase in $\tau^{-1}$, the changes in the distributional variables are the following: std.(log([prices])) = 0.01, 99-to-50 percentile ratio of log([prices]) = −0.02 whereas std.(log([sales])) = 67.83, 99-to-50 percentile ratio of log([sales]) = 40.45.
observe little changes in the dispersion of log(prices) but larger changes in the dispersion of log(sales) after the trade cost shock.

7. Conclusion

In this paper, we analyzed a model that contains three mechanisms that contribute to price dispersion across firms and countries. These mechanisms include firm heterogeneity in productivity, non-homothetic preferences that give rise to variable markups, and a “Washington Apples” mechanism that features specific trade costs and quality choice by producers. These three mechanisms allow our model to fit well the rich pattern of cross-country and cross-firm price variation observed in the data.

A nice feature of our model is that incorporates specific trade costs into a quantitative framework in a simple manner. An important implication of adding specific trade costs is that there are now two distinct trade elasticities that arise. Cost shifters that act as ad-valorem trade costs imply a lower elasticity than cost shifters that act as specific-trade costs. In the absence of a way of categorizing trade costs, standard gravity equation analysis is problematic. To overcome this, we showed

Fig. 8. Different role of T and τ on export prices. Notes: y-axis is average destination (log) price increase after the shock.
that the aggregate trade elasticity could still be recovered from variation in markups as in Jung et al. (2019).

We also showed that the relationship between export prices and the gains from trade depends substantially on the nature of trade costs. Specifically, among trade cost shocks with equivalent welfare implications, shocks to specific trade costs generated outsized shifts in export prices while shocks to ad valorem trade costs had little impact on these prices.

Going forward, we hope that research in the field of international trade will become more cognizant of the importance of modeling trade costs more flexibly. We hope that our framework will encourage more research by demonstrating the potential quantitative importance of specific trade costs and by showing that it is possible to write down relatively simple models that allow for both firm heterogeneity and non-iceberg-type variable trade costs.
